Bayesian Probit Regression

All code for this project can be found at https://github.com/k-m-li/biostat-276-2022-fall # 1) Let's compute our target distribution:

$$p(\vec{\beta}|\vec{y}) \propto p(\vec{y}|\vec{\beta})p(\vec{\beta})$$

$$= \prod_{i=1}^{n} (p_i^{y_i} (1 - p_i)^{1 - y_i}) \exp[-\frac{1}{2} \vec{\beta}^T (100(X^T X)^{-1})^{-1} \vec{\beta}]$$

Our MCMC generates symmetric proposals about the current β :

$$\hat{\beta}_{i+1} \sim N(\beta_i, 10^2 (X^T X)^{-1})$$

With acceptance criteria:

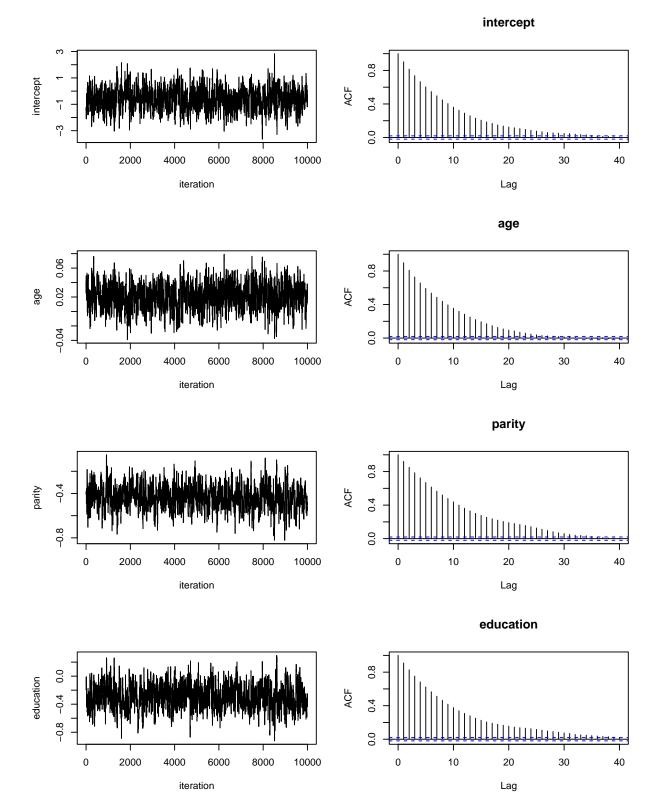

$$u \sim U(0, 1)$$

$$\alpha = \frac{p(\hat{\beta}_{i+1}|\vec{y})}{p(\beta_i|\vec{y})}$$

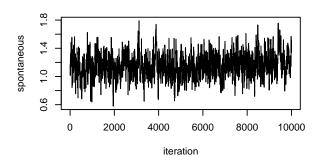

$$\beta_{i+1} = \begin{cases} \hat{\beta}_{i+1} & u \leq \alpha \\ \beta_i & u > \alpha \end{cases}$$

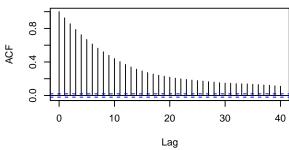

```
n.total <- n.sim*(1.0 + burn)
  n.burn <- n.sim*burn
  #initialize chain
  beta.out <- matrix(NA, nrow = n.sim, ncol = p)</pre>
  beta <- beta0
  for(i in 1:n.total){
    beta new <- rmvnorm(1, mean = beta,
                         sigma = xtx.inv) %>% t()
    loglik_new <- getLogLik(y, x, xtx, beta_new)</pre>
    loglik_old <- getLogLik(y, x, xtx, beta)</pre>
    logdiff <- loglik_new - loglik_old</pre>
    #accept-reject
    if(log(runif(1)) < logdiff){</pre>
      beta <- beta_new
    if(i > n.burn){
      i1 <- i - n.burn
      beta.out[i1, ] <- beta</pre>
    }
  }
  colnames(beta.out) <- c("intercept", "age", "parity",</pre>
                            "education", "spontaneous", "induced")
  return(beta.out)
beta0 <- solve(t(x) %*% x) %*% t(x) %*% y
mh.out <- adaptive.mh(10000, 0.1, x, y, beta0)</pre>
mean <- colMeans(mh.out)</pre>
sd <- apply(mh.out, 2, sd)</pre>
cbind(mean, sd) %>% kable(linesep = "")
```

2)

Let $z_i \sim^{iid} N(\vec{x_i}^T \vec{\beta}, 1)$. Now: $P(y_i = 1 | \vec{x_i}, \vec{\beta}) = P(\mathbf{1}(z_i > 0) = 1) = P(z_i = 0)$ $P(\vec{\beta} | \vec{z}, \vec{y}) \propto p(\vec{y}, \vec{z} | \vec{\beta}) p(\vec{\beta})$ $\propto p(z | \vec{\beta}) p(\vec{\beta})$ $= N(X\vec{\beta}, I) N(0, 100(X^T X)^{-1})$ $\propto \exp[-\frac{1}{2}(\vec{z} - X\vec{\beta})^T (\vec{z} - X\vec{\beta})] \exp[-\frac{1}{2}\vec{\beta}^T (100(X^T X)^{-1})^{-1}\vec{\beta}]$ $\propto \exp[-\frac{1}{2}(\vec{\beta}(\frac{100}{101}(X^T X)^{-1})^{-1}\vec{\beta} - 2\vec{\beta}^T X^T \vec{z})]$

By definition, $\vec{\beta}|\vec{z}, \vec{y} \sim N(\frac{100}{101}(X^TX)^{-1}X^T\vec{z}, \frac{100}{101}(X^TX)^{-1})$. Also:

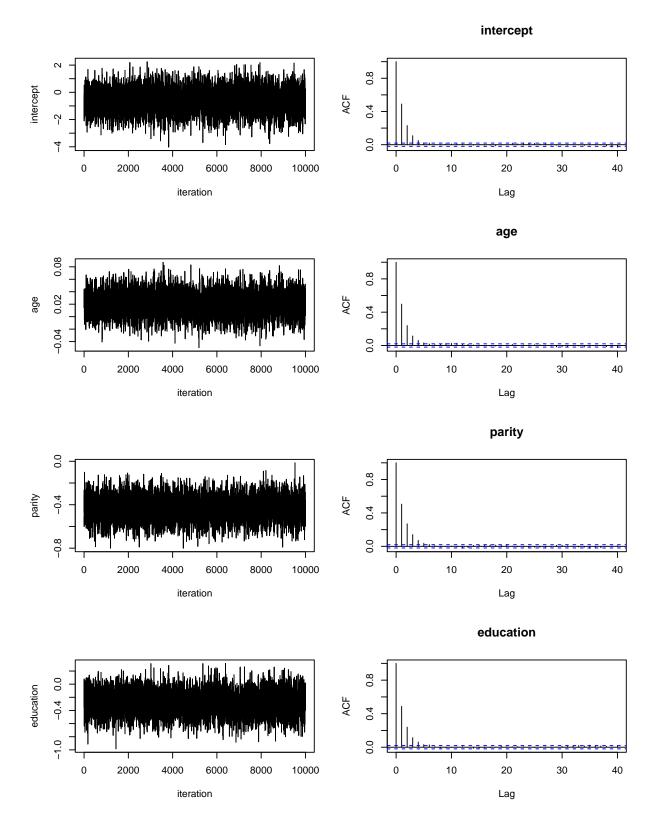

$$z_{i}|\vec{\beta}, y_{i} \propto p(y_{i}|\vec{\beta}, z_{i})p(z_{i}|\vec{\beta})$$

$$= \begin{cases} N(\vec{x_{i}}^{T}\vec{\beta}, 1) * \mathbf{1}_{[0,\infty)}(z_{i}) & y_{i} = 1\\ N(\vec{x_{i}}^{T}\vec{\beta}, 1) * \mathbf{1}_{(-\infty,0]}(z_{i}) & y_{i} = 0 \end{cases}$$

Then, we can implement DA-MCMC by Gibbs sampling $p(\vec{\beta}, \vec{z}, \vec{y})$ and $p(\vec{z}|\vec{\beta}, \vec{y})$:

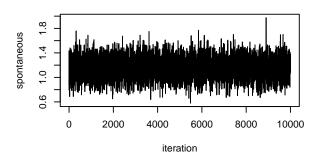

```
da.mcmc <- function(n.sim, burn, x, y, beta0){</pre>
  #matrix stuff
  n <- length(y)
  p \leftarrow ncol(x)
  xtx <- t(x) %*% x
  xtx.inv <- solve(xtx)</pre>
  var <- 100/101 * xtx.inv</pre>
  #chain information
  n.total <- n.sim*(1.0 + burn)
  n.burn <- n.sim*burn
  #initialize chain
  z \leftarrow rmvnorm(1, x%*\%beta0, diag(1, nrow = n))
  beta <- beta0
  beta.out <- matrix(NA, nrow = n.sim, ncol = p)
  #beta
  for(i in 1:n.total){
    beta <- rmvnorm(1, var %*% t(x) %*% t(z), var) %>% t()
    for(j in 1:n){
      if(y[j] == 1){
      z[j] \leftarrow rtruncnorm(1, a = 0, b = Inf, mean = x[j,] %*% beta, sd = 1)
      z[j] \leftarrow rtruncnorm(1, a = -Inf, b = 0, mean = x[j,] %*% beta, sd = 1)
  #store variables after burn
    if(i > n.burn){
```

Let's introduce another parameter $\alpha^2 \sim \text{Inverse Gamma}(a,b)$. Let $W_i = \alpha Z_i$. We now sample from the following distributions using Gibbs:

$$\begin{split} \vec{\beta}|\vec{w},\alpha,\vec{y} \sim N(\frac{101}{100}(X^TX)^{-1}\frac{X^t\vec{w}}{\alpha},\frac{101}{100}(X^TX)^{-1})) \\ w_i|\vec{y}\vec{\beta}\alpha &= \begin{cases} N(\alpha\vec{x_i}^T\vec{\beta},\alpha^2) * \mathbf{1}_{[0,\infty)}(w_i) & y_i = 1\\ N(\alpha\vec{x_i}^T\vec{\beta},\alpha^2) * \mathbf{1}_{(-\infty,0]}(w_i) & y_i = 0 \end{cases} \\ p(\alpha^2|\vec{w},\vec{\beta},\vec{y}) \propto \exp[-\frac{1}{2}(\frac{\vec{w}^t\vec{w}}{\alpha^2} - \frac{2\vec{\beta}^TX^T\vec{w}}{\alpha})]\alpha^{2^{-a-1}}\exp[-\frac{b}{\alpha^2}] \\ \log p(\alpha^2|\vec{w},\vec{\beta},\vec{y}) \propto -\frac{1}{2}\frac{\vec{w}^T\vec{w}}{\alpha^2} + \frac{\vec{\beta}^TX^T\vec{w}}{\alpha} - (a+1)\log(\alpha^2) - \frac{b}{\alpha^2} \\ \log p(\alpha^2) \propto -(a+1)\log(\alpha^2) - \frac{b}{\alpha^2} \end{split}$$

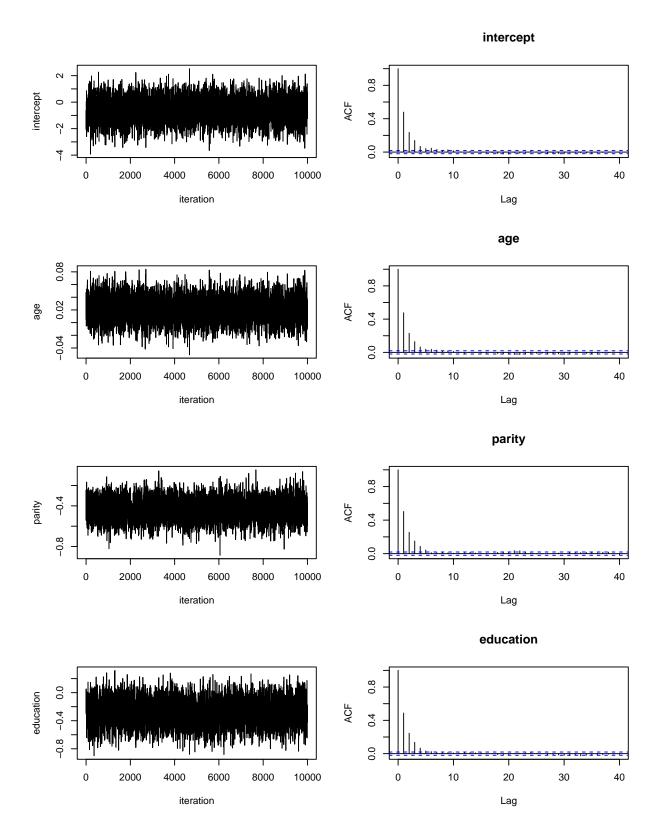

To sample using Metropolis-Hastings for α^2 , we sample from the centered distribution with some tuning parameter c:

 $\alpha_{i+1} \sim \text{Inverse Gamma}(c, \alpha_i^2(c+1))$

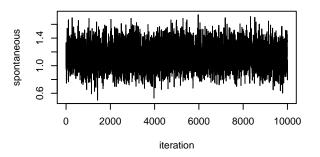

```
getLogLikIG <- function(alpha2, a, b){</pre>
  loglik \leftarrow (-a + 1) * log(alpha2) - b/alpha2
  return(loglik)
getLogLikAlpha <- function(x, alpha2, w, beta, a, b){</pre>
  loglik = -1/2 * sum(w^2)/alpha2 + t(beta) ** t(x) ** w/sqrt(alpha2) - (a + 1)*log(alpha2) - b/alpha
  return(loglik)

4)

Function	Elapsed time (sec)	Total RAM used (MiB)	Peak RAM used (MiB)
AMH	3.55	0.6	32.5
DA-MCMC	22.64	0.5	37.1
PX-DA-MCMC	23.36	0.5	37.1

All three algorithms converged to similar coefficients with 10,000 simulations and 1,000 burn-in iterations. However, AMH had significantly worse mixture than the other two algorithms, based off the ACF plots. Regarding coding complexity, AMH was the simplest to implement, with the lowest efficiency, followed by DA-MCMC and then PX-DA-MCMC. On run-time and RAM usage, AMH had the lowest of both, with the other two algorithms very similar in both time and storage, but higher. In our case, all three algorithms still converged and DA-MCMC / PX-DA-MCMC did not have strong differences in mixture, DA-MCMC may be the "best of both worlds" in being relatively straightforward to implement, while giving us an idea of the entire posterior distribution for our parameters of interest.
